Retroperitoneal ganglioneuroma in an adult
Madeleine Louise Kelly, Pranavan Palamuthusingam

ABSTRACT

Introduction: Retroperitoneal ganglioneuromas (GNs) are rare, benign neural tumors of the sympathetic nervous system.

Case Report: A 57-year-old female presented with a two-week history of recurrent lower left sided back pain. Radiological investigations revealed a large paraaortic mass measuring 67 by 50 mm, extending from the adrenal gland to the mid lower pole of the left kidney, without lymphadenopathy elsewhere. Histopathological examination identified fragments composed of fibrous tissue, little adipose tissue with bland spindled cells and occasional ganglion cells, suggestive of ganglioneuroma. The decision was made for active surveillance over surgical excision.

Conclusion: Due to its rare nature and the nonspecific clinical signs, arriving at a definitive diagnosis remains a challenge for clinicians and no gold standard approach has been suggested.

Keywords: Adult, Diagnosis, Management, Retroperitoneal ganglioneuroma.

CASE REPORT

A 57-year-old female presented with a two-week history of left sided lower back pain associated with night sweats. No other constitutional symptoms were reported, and the patient's physical examination was unremarkable. Past medical history of note included ischemic heart disease managed medically. The patient's blood panel was within normal ranges, of note, serum electrolyte and hormonal studies (including CgA and plasma metanephrines) were normal, confirming the non-functional nature of the mass. Computed tomography (CT) revealed a large paraaortic mass, measuring 67 by 50 mm, extending from the adrenal gland to the mid lower pole of the left kidney (Figure 1A and B). The mass enveloped the coeliac axis and superior mesenteric artery (SMA). No lymphadenopathy elsewhere was shown on positron emission tomography (PET) scan and fluorodeoxyglucose avidity was relatively low at 3.36, suggestive of no metabolic activity. Computed tomography guided biopsy of the mass was performed with the specimen sent for histopathological examination. This identified fragments composed of fibrous tissue and little adipose tissue with bland spindled cells (Figure 2A) and occasional ganglion cells.

How to cite this article
(Figure 2B). No atypia or mitotic activity was evident. Flow cytometry was inconclusive for surface marker analysis. Histopathological examination was consistent with a diagnosis of ganglioneuroma. Due to the extensive vascular involvement of the coeliac axis and superior mesenteric artery, surgical excision was not considered to be appropriate and instead, due to the benign nature of the tumor and the mild symptomatology of back pain, regular surveillance was preferred. The plan for follow-up was for annual CT bought forward if symptomatology worsened, with re-evaluation of the surgical plan if required. Since diagnosis the patient has experienced an episode of back pain every six months, which resolves within a week. Further radiological imaging showed a stable lesion, with minimal growth, with a maximal transverse diameter of 81 mm and maximal height of 94.5 mm (Figure 1C). This case highlights a rare cause of back pain and retroperitoneal mass in an adult, and the diagnostic challenge that arises with this rare tumor.

**DISCUSSION**

Retroperitoneal ganglioneuromas (GNs) are a rare, benign tumor of neural crest origin, commonly arising from anywhere along the sympathetic plexus, and occasionally in the adrenal medulla [1, 2]. It is commonly found in the posterior mediastinum (41.5%) or the retroperitoneum (37.5%) [3–5]. Typically, GN arises spontaneously in the sympathetic ganglion but can occur during radiation or chemotherapy. Traditionally affecting females more than males, GN tumors are composed of mature Schwann cells, ganglion cells, and nerve fibers [1, 6]. Mostly of sporadic origin, some familial predisposition has been documented and there is an association with Turner’s syndrome and multiple endocrine neoplasia II [7].

Most GN tumors are asymptomatic. Rarely the tumor will be diagnosed due to its secretory activity of catecholamines, vasoactive intestinal polypeptides, or androgenic hormones, producing symptomatology of hypertension, diarrhea, and virilization. The compressive effects of the tumor on neighboring tissues can also cause complications. The slow growth pattern of GN tumors results in diagnosis more commonly in older children and young adults [1, 6].

Given its asymptomatic nature and lack of specific diagnostic methods, imaging plays an important role in diagnosing disease. Computed tomography, ultrasound, and magnetic resonance imaging show a well-circumscribed, oval, lobulated mass. Ultrasound reveals a homogenous, hypoechoic, mass while an unenhanced CT will show a low attenuation, homogenous mass. Calcifications are seen in about 20% of cases [6]. Ganglioneuromas tend to surround or displace major blood vessels but do not cause occlusion or compression [1]. There are no specific radiological findings for GN tumors making differentiation from other tumors difficult and often only possible with histological examination of the resected mass postoperatively. Cellular atypia, mitotic activity, and necrosis are not observed on histopathological examination [8]. Definitive diagnosis is confirmed after pathological examination of the specimen.

Gold standard management remains to be determined with questions arising as to whether surveillance or surgical excision of an asymptomatic, benign lesion is preferred. With most tumors discovered incidentally while investigating nonspecific symptoms, currently there are no surveillance guidelines for retroperitoneal GN [6, 9]. Reports have suggested that for tumors less than 6 cm in size with no metabolic activity or for tumors not amenable to complete resection that conservative follow-up is an appropriate option but time intervals vary, guided by patient symptoms [10]. Other reports suggest due to the difficult preoperative diagnostic nature of this lesion, that surgical resection is best especially in cases of marked growth in tumor size, increased secretory activity, or encroachment on vertebral foramina [1, 9, 10]. Potential alternative interventions include fractionated...
resection of GN that surround major vessels and transarterial embolization using both microparticles and a liquid embolic agent, a technique that may be a safe and effective option, particularly for symptomatic relief [11]. In general, surgery is the only potential curative treatment, with a low reoccurrence rate after tumor resection.

CONCLUSION

Retroperitoneal ganglioneuromas are well differentiated benign tumors that are typically hormonally inactive. Although an uncommon lesion in adults, it should be considered among potential diagnosis for any retroperitoneal mass. Due to its rare nature, radiological and pathological investigations provide important diagnostic information for effective management; however, the gold standard management is yet to be determined. Guidelines on surveillance versus surgical resection remain dependent on patient preference and the symptomatic effect on patient quality of life. Retroperitoneal ganglioneuromas removed surgically have an excellent prognostic outcome.
